Abstract

We consider how the domination number of an undirected graph changes on the removal of a maximal matching. It is straightforward that there are graphs where no matching removal increases the domination number, and where some matching removal doubles the domination number. We show that in a nontrivial tree there is always a matching removal that increases the domination number; and if a graph has domination number at least 2 there is always a maximal matching removal that does not double the domination number. We show that these results are sharp and discuss related questions.

Chapter 1

Introduction

We begin by discussing relevant definitions and known results. For the purpose of this thesis, we assume that a graph $G = (V, E)$, defined by vertex set $V$ and edge set $E$, is simple and undirected. There are three essential topics in the theory of graphs necessary to understand our results. We explore each in depth, beginning with Domination in graphs. We introduce known results about dominating sets and present some standard proofs. We then discuss operations performed on graphs which change the domination number. Lastly in this introduction, we discuss matchings in graphs, presenting some well known results. Chapter 2 will then discuss the main results and Chapter 3 will pose some open questions.

1.1 Domination in Graphs

We define a dominating set, $D$, of a graph to be a subset of the vertex set such that every vertex of $G$ is either in $D$, or is adjacent to a vertex in $D$. We can give an equivalent definition using the closed neighborhood of a vertex $v$, denoted by $N[v]$. The closed neighborhood of a vertex $v$ is defined to be all vertices adjacent to $v$, including $v$ itself (note if we want the neighborhood without $v$, we call this the open neighborhood of $v$, denoted $N(v)$). We can extend this to the closed neighborhood of a vertex subset $D$ denoted $N[D]$ as the union of closed neighborhoods of vertices in $D$ (the open neighborhood of a vertex subset $D$ denoted $N(D)$ is defined similarly). As such, a dominating set can be defined equivalently as a set $D$ such that the removal $N[D]$ leaves the empty graph. We define the domination number of $G$ to be the minimum cardinality among all dominating
sets and denote it $\gamma(G)$. As such, we call a dominating set a $\gamma$-set.

In the introduction of [8] the authors include a review of the historical development of domination in graphs. The classic motivating example is the Dominating Queens, or the $n$–Queens Problem. The authors note that the original problem posed in the 1850s was to determine the minimum number of queens needed to be placed on a chessboard so that all squares are either attacked by a queen or are occupied by a queen. For a standard $8 \times 8$ chessboard this number is 5; however, the problem has been generalized extensively to different sized boards, and boards with holes. The problem is equivalent to taking the queen’s graph representing all legal moves of a queen on a chessboard and finding a minimum dominating set.

Clearly, the existence of a dominating set is trivial as one could take the entire vertex set. However, the complexity of finding $\gamma(G)$ in general is known to be an NP-hard problem (with a proof provided in [8]). There are variations of the domination number that are also extensively studied including the total domination number and the independent domination number; however, those are not discussed here.

The following gives an upper bound on the domination number of a graph with a version of the standard proof.

**Theorem 1.** Given a connected graph $G$ of order $n \geq 2$, $\gamma(G) \leq \frac{n}{2}$ [10].

**Proof.** Let $D$ be a minimum dominating set of a graph $G$. Define $X$ to be vertices of $G$ not in $D$. We first claim that $X$ is also a dominating set. Assume that there is some $v \in D$ such that $v$ does not have a neighbor in $X$. Then all neighbors of $v$ are in $D$ and so $D \setminus \{v\}$ is also a dominating set which contradicts minimality. So $X$ is also a dominating set. Note now if $D$ contained more than half of the vertices of $G$ then $X$ would be a smaller dominating set. So $D$ is at most half the order of $G$.

This bound is sharp. Given a graph $G$, we define the $k$-corona of $G$ as the graph obtained by, for each vertex, adding $k$ new end-vertices adjacent to that vertex. If $k = 1$ we call it simply the corona. The previous bound is attained by the corona of a graph. In Figure 1.1 we give an example of the corona of $P_5$. Note that the original $P_5$ vertices form a minimum dominating set of size half the order of the corona.
1.2 Bondage in Graphs

One fundamental area of study as regards the domination number of a graph is how it changes under graph operations. In particular, both the removal of vertices, and the removal or addition of edges, have been the focus of many papers. For example, vertex-critical graphs are ones where the deletion of any vertex decreases the domination number (see for example [4]) while critical graphs are ones where the addition of any edge decreases the domination number (see for example [11]). One specific parameter in this regard is the bondage number of a graph (denoted $b(G)$) which is defined to be the minimum number of edges whose removal increases the domination number. The following result gives a bound on the bondage number of a tree. The proof by the original authors in [5] is included to illustrate which edges are chosen to remove.

**Theorem 2.** If $T$ is a nontrival tree, then $b(T) \leq 2$ [5].

**Proof.** The statement is obviously true for trees of order 2 or 3; so we shall suppose that $T$ has at least 4 vertices.

Suppose first that $T$ has a vertex $u$ that is adjacent to two end-vertices $v$ and $w$ (and possibly more). If $D$ is a dominating set for $T$ that does not contain $u$, then $D$ contains both $v$ and $w$; but then, $(D \setminus \{v, w\}) \cup \{u\}$ is also a dominating set for $T$. Thus every minimum dominating set for $T$ contains the vertex $u$ and therefore does not contain $v$. Since every dominating set of $T - uv$ contains $v$ and is also a dominating set for $T$, it follows that $\gamma(T - uv) > \gamma(T)$. Hence $b(T) = 1$ in this case.

Suppose now that each vertex of $T$ is adjacent with exactly one end-vertex. Then $T$ has a vertex $u$ of degree 2 that is adjacent with exactly one end-vertex $v$. Let $w$ be the other vertex adjacent to $u$, and let $D$ be a minimum dominating set for $T - uv - uw$. Then both $u$ and $v$ are in $D$ and $D \setminus \{v\}$ is a dominating set for $T$. Hence $\gamma(T) < \gamma(T - uv - uw)$ and $b(T) \leq 2$. \qed
Note that we see in the second case the authors removed two edges incident with \( u \). This is not necessary; that is, if a graph has bondage number 2 then we can always find two independent edges.

**Theorem 3.** For a tree \( T \) with bondage number 2 one can find a bondage set of independent edges.

**Proof.** First note that if \( T \) is the path \( P_n \) then \( n \equiv 1 \pmod{3} \) otherwise it has bondage 1. One can verify that in this case removing both (necessarily independent) edges incident with leaves increases the domination number.

So assume \( T \) is not a path. We note that for trees, the packing number and domination number are equal [9]. Note further that trees with bondage 2 are exactly those with a unique maximum packing [7]. Concerning trees with unique maximum packing, every leaf vertex is included in our packing (if not, then given a leaf not in the packing, add it and remove the vertex in the packing closest to it, contradicting uniqueness). For \( T \) not a path, we can still remove two independent edges such that the resulting forest has higher domination number.

Root \( T \) at some end vertex, \( r \). Find a vertex \( x \) with \( \deg(x) \geq 3 \) such that it is farthest from \( r \). There must exist paths \( P_i \) of lengths \( p_i \) to end vertices \( v_i \) for \( i \in \{1, 2\} \) such that other than \( x \) and \( v_i \) all vertices have degree 2. These can be found by traveling further down our rooted tree, by choice of \( x \). Note that \( v_1 \) and \( v_2 \) cannot both be leaf vertices else we contradict \( T \) with bondage number 2.

**Case 1:** Some \( P_1 \) has length \( p_1 \geq 3 \). As stated above, since we have bondage 2 we have a unique maximum packing containing leaf vertices. Considering the path from \( v_1 \) to \( x \), remove the first and third edge. A new packing contains the isolate, one of the vertices from the \( P_2 \) component, and vertices from the original packing in the third component. The third component has packing number one less than the original tree and so the domination number has increased and we have an independent bondage set.

**Case 2:** Without loss of generality \( p_1 = 1 \) and \( p_2 = 2 \). We claim that the leaf edges incident with \( v_1 \) and \( v_2 \) form a bondage set. Upon removal we have \( v_1 \) and \( v_2 \) in our packing, and can additionally add the support vertex of \( v_2 \) since \( v_1 \) was in the original packing. So we have two isolates in our packing, and the nontrivial component has decreased its packing size by 1. Thus the edges form an independent bondage set.

**Case 3:** Consider \( p_1 = p_2 = 2 \). If \( x \) has no neighbor in the packing then we again remove
both leaf edges and as in case 2 we add a new leaf vertex to the packing and notice we indeed have
an independent bondage set of size 2. So suppose $x$ does have a neighbor in the packing; call it $y$.
In this case remove the edge incident with $v_1$ and the edge between $x$ and $y$. Then $v_1$ is in our new
packing and we can include the new leaf formed by removing $v_1$ since $x$ no longer has a neighbor in
the packing. So again we have found an independent bondage set.

We study an extension of edge removal by considering what happens when one removes
a matching from a graph, where a matching is defined in the following chapter. We see in what
follows that removing matchings puts on the restriction that at most one edge incident to a vertex
is removed.

1.3 Matchings in Graphs

We now introduce the concept of a matching. A matching is a subset of the edge set of a
graph such that each vertex is incident to at most one edge. We define the matching number of
a graph $G$ to be the maximum cardinality of a matching and denote it $M(G)$. There are a few
different types of matchings that will be relevant:

- A perfect matching is a matching in which every vertex is incident to an edge in our matching.
- A maximal matching is a matching such that no proper super set of edges is a matching.
- A maximum matching is a matching with greatest cardinality among all matchings of a graph.

We note that perfect matchings can only occur in graphs of even order and that they are
necessarily maximum and maximal with size $|V(G)|/2$ (where $|V(G)|$ denotes the number of vertices
of $G$, also called the order of $G$, denoted $|G|$). Maximum matchings are always maximal; however,
the converse is not true. An example is given in Figure 1.2.

In the section that follows, the above tree and matching will prove interesting as we discuss
how the removal of a matching affects the domination number. For further examples of matchings,
Figure 2.1 in the following section shows a tree with multiple maximal matchings of different sizes.

The following standard result gives some intuition that was useful for considering matchings
in trees. A proof is provided to supplement the intuition. One needs that an augmenting path of
a matching is one that starts with an unmatched edge and alternates between matched edges and unmatched edges, ending at another unmatched edge. Berge observed that if we can find such a path then removing matched edges from the matching and adding unmatched edges increases the size of the matching.

**Lemma 1.** Every maximum matching on a tree $T$ has an edge incident to a leaf.

**Proof.** Let $M$ be a maximum matching and assume for a contradiction that no leaf is matched by $M$. This is not perfect by definition, so let $v$ be unmatched. Move along its unmatched edge to another vertex, say $v_2$. Vertex $v_2$ must be matched, else we can increase our matching which contradicts $M$ maximum. We follow the matched edge incident to $v_2$ to its matched neighbor $v_3$. If $v_3$ has no neighbors then $v_3$ is a leaf and we have found a matched leaf. Else we continue the pattern. Since $T$ is a finite tree, we must terminate at some vertex with no neighbors and so we terminate at a leaf. If we terminate at an unmatched vertex $v_n$ then $v_1, v_2, ..., v_n$ gives an augmenting path which contradicts $M$ being a maximum matching. So we must terminate at a matched vertex; that is, we terminate at a matched leaf.

$\square$
Chapter 2

Results

We now discuss the results that make up the bulk of this thesis. This chapter was accepted for publication; see [2]. Even for trees, the question of how much or how little the least-impact or the most-impact matching changes the domination number seems interesting. For example, we show that: (a) for a tree there always exists a matching whose removal increases the domination number (indeed any maximum matching suffices); (b) there are trees of arbitrarily large domination number where no matching removal increases it by more than 1; (c) in any graph a matching removal can at most double the domination number; and (d) while there is no graph with domination number bigger than 1 where for every maximal matching its removal doubles the domination number, there are trees of arbitrarily large domination number $r$ where the removal of any maximal matching increases the domination number to at least $2r - 1$.

2.1 The Fundamentals

The removal of a matching can both change and not change the domination number. There are graphs, such as the 5-cycle, where removing any matching does not change the domination number. Or, for example, if the 2-domination number of a graph (meaning the smallest size of a set $D$ such that every vertex outside $D$ has at least two neighbor in $D$) equals its domination number, then the removal of a matching cannot change the domination number. But there are graphs, such as the complete graph $K_n$ for $n$ even, where the removal of any maximal matching does increase the domination number.
There is a simple limit though on how much the removal of a matching can increase the domination number. Since each vertex in a dominating set loses at most one neighbor, one immediately has:

**Lemma 2.** Removing a matching from a graph can at most double the domination number of the graph.

For example, Figure 2.1 shows a tree \( T \) with \( \gamma(T) = 3 \), where there are maximal matchings \( M_3 = \{c, d\} \), \( M_4 = \{c, e\} \), \( M_5 = \{a, b, d\} \), and \( M_6 = \{a, b, e\} \) such that \( \gamma(T - M_i) = i \) for \( 3 \leq i \leq 6 \).

![Figure 2.1: A tree with multiple maximal matchings](image)

Now, in the case that one is removing a matching that has the most impact (that is, increases the domination number as much as possible), it is immediate that one may assume that the matching is maximal. On the other hand, in the case where one is removing a matching that has the least impact, it is necessary to add some condition on the matching, else the empty matching will be the answer. In this paper:

*The focus is on the case that the matching is maximal.*

Some of the results apply to all matchings, and so we state them as such. We also occasionally consider the case that the matching is required to be maximum, but this is a different problem. For example, Figure 2.2 shows a tree that has a unique maximum matching up to symmetry, and removing it increases the domination number from 3 to 5. On the other hand, removing the depicted maximal matching, consisting of two leaf-edges and the central edge, increases the domination number to 6. In general we use end-vertex to mean a vertex of degree 1, and leaf-edge to mean an edge incident to such a vertex.

There is a partial connection with the bondage number. If the bondage number of a graph is 1, then it is immediate that the removal of any matching containing that one edge increases the domination number. As noted above, a tree has bondage number at most 2, but the two edges might need to be adjacent. With matchings, our edges must be independent.
As stated previously, it is well-known that the domination number of a graph without isolates is at most half its order. One can ask a similar question for a matching-deleted graph:

**Theorem 4.** If $G$ is a connected graph of order $n \geq 3$ and $M$ a matching of $G$, then $\gamma(G - M) \leq \frac{3n}{4}$.

**Proof.** Since the removal of an edge cannot decrease the domination number, we may assume $G$ is a tree. The proof is by induction on the order $n$. If $G$ is a star, then $\gamma(G - M) = 2$. So we may assume $G$ is not a star. If $G$ has diameter 3, then $\gamma(G) = 2$ and so $\gamma(G - M) \leq 4$. The bound follows if $n \geq 6$. But it can be easily checked that the bound is true if $n$ is 4 or 5. So we may assume that $G$ has diameter at least 4. Consider a longest path $P$ in $G$ with penultimate vertex $v$.

**Case 1:** Vertex $v$ has at least two end-vertex neighbors. Then let $L$ be the set consisting of $v$ and its end-vertex neighbors. In $G - M$ it is still possible to dominate $L$ using at most two vertices. Let $G' = G - L$, and let $M'$ be the matching $M$ restricted to $V(G')$. Since $G$ has diameter at least 4, the graph $G'$ has at least three vertices. So by the induction hypothesis, $G' - M'$ can be dominated with at most $\frac{3}{4}$ its order. It follows that $\gamma(G - M) < 2 + 3(n - |L|)/4 < \frac{3n}{4}$.

**Case 2:** For all choices of $P$, vertex $v$ has exactly one end-vertex neighbor. That is, it has degree 2 in $G$. Let $w$ be the other neighbor of $v$, and $x$ the other neighbor of $w$ on $P$. If $P$ has length 5 or more, then let $J$ be the set of vertices separated from $x$ by the bridge $xw$. Then let $G' = G - J$ and let $M'$ be the matching $M$ restricted to $V(G')$. By the induction hypothesis, $G' - M'$ can be dominated with at most $\frac{3}{4}$ its order. If $P$ has length 4, then let $J = V(G)$ and vacuously the graph $G' = G - J$ can be dominated with at most $\frac{3}{4}$ its order.

Say $J$ contains $\ell$ neighbors of $w$ of degree 1 and $t$ neighbors of $w$ of degree 2. (Since we are in Case 2 it holds that $t \geq 1$.) Note that $|J| = 2t + \ell + 1$. If $\ell = 0$, in $G - M$ one can dominate $J$ with at most $t + 1$ vertices; since $(t+1) < 3(2t+1)/4$ it follows that then $\gamma(G - M) < 3|J|/4 + 3|G'|/4 = 3n/4$. If $\ell > 0$, in $G - M$ one can dominate $J$ with at most $t + 2$ vertices; since $(t + 2) \leq 3(2t + 2)/4$ it
follows that then $\gamma(G - M) \leq 3|J|/4 + 3|G'|/4 = 3n/4$.

The bound in Theorem 4 is best possible and is achieved for the corona of a corona of a graph. Figure 2.3 shows an example where removing all leaf-edges increases the domination number to 15.

\[

\]

### 2.2 Matchings Whose Removal (Almost) Double the Domination Number

In this section we provide some insight into the maximum change that removing a matching can cause. Consider for example a tree $T$ where every vertex in the (necessarily unique) $\gamma$-set has (at least) two end-vertex neighbors. Fink et al. [5] observed that for such a tree the bondage number is 1. We note that if $M$ is a matching consisting of a leaf-edge incident with each vertex in the dominating set, it is immediate that $\gamma(T - M) = 2\gamma(T)$.

There is a bound on the domination number of graphs that have a matching whose removal doubles the domination number. We will need the following terminology: given a vertex set $D$ and a vertex $v$ of $D$, an external private neighbor of $v$ with respect to $D$ is defined to be a vertex outside $D$ whose only neighbor in $D$ is $v$.

**Theorem 5.** If a connected graph $G$ with order $n \geq 3$ has a matching $M$ such that $\gamma(G - M) = 2\gamma(G)$, then $\gamma(G) \leq n/3$.

**Proof.** Consider a $\gamma$-set $D$ of $G$; we can choose $D$ to not contain an end-vertex. For each vertex $v \in D$, if $v$ is incident with an edge of $M$ then let $v'$ be the end of that edge. Let the set $X$ consist of $D$ and all the $v'$. This set dominates $G - M$. By the hypothesis, this means $|X| = 2|D|$, so that all the vertices $v'$ exist; that is, every vertex of $D$ is incident with $M$. Further, the set $X$ must be
minimal dominating. So it follows that each \( v' \) has no neighbor in \( D - v \); that is, in \( G \) the vertex \( v' \) is an external private neighbor of \( v \) with respect to \( D \).

Let \( D' \) be the set of vertices of \( D \) that have only one external private neighbor in \( G \). If \( D' \) is nonempty, consider any vertex \( v \in D' \). By the choice of \( D \), the vertex \( v \) is not an end-vertex and thus has a neighbor other than \( v' \), say \( w \). Since the set \( X \) is minimal dominating in \( G - M \), and vertex \( v \) is in \( X \) only to dominate itself, it must be that \( w \) is not in \( D \). Further, we claim that \( w \) has only one neighbor in \( D' \). Since, if \( w \) also has neighbor \( u \in D' \), one can take \( X \) and replace \( u, v \) by \( w \) and get a smaller dominating set, which is a contradiction.

For each vertex \( v \in D' \), define the triple \( R_v = \{v, v', w\} \). For each vertex \( v \in D - D' \), define the triple \( R_v \) as \( v \) and two of its external private neighbors in \( G \). By the above discussion these triples are disjoint. Thus the order of \( G \) is at least \( 3|D| \), whence the desired bound.

\( \square \)

There are graphs and indeed trees that achieve the bound in Theorem 5. The simplest example is the 2-corona of any graph; an example is shown in Figure 2.4. But another example is given in Figure 2.1.

![Figure 2.4: A 2-corona](image)

It is also natural to look for graphs where the removal of any maximum matching doubles the domination number. Or even stronger, where the removal of any maximal matching doubles the domination number.

The graphs with domination number 1 are a special case. If a graph has domination number 1 and even order, then the removal of any maximal matching \( M \) increases the domination number to 2. For suppose there is a still a dominating vertex \( v \) after the removal of \( M \). Then \( v \) is not covered by \( M \), and since the order is even, there is another uncovered vertex, necessarily a neighbor of \( v \), which contradicts the maximality of \( M \). If a graph has domination 1 and odd order, then both possibilities can occur. For example, the removal of any maximal/maximum matching from a star increases the domination number; but the removal of any maximal/maximum matching from a complete graph keeps it at 1.
So consider graphs with domination number at least 2. Here there are graphs where the removal of any maximum matching doubles the domination number. For example, define the octopus $O_r$ by taking the star $K_{1,r}$ and subdividing every edge except one exactly three times. The result has $\gamma(O_r) = r$, achieved uniquely by taking the support vertices (where a support vertex is defined as one with an end-vertex neighbor). Further, the graph has a unique perfect matching, and its removal increases the domination number to $2r$. Figure 2.5 shows $O_5$.

![Figure 2.5: The octopus $O_5$](image)

But the situation is (slightly) different if one considers all maximal matchings:

**Theorem 6.** If $G$ is a connected graph with $\gamma(G) > 1$, then there exists a maximal matching $M$ such that $\gamma(G - M) < 2\gamma(G)$.

**Proof.** Consider a $\gamma$-set $D$ of $G$. If $G$ is not a tree, choose a spanning tree $T$ such that $D$ dominates $T$. It then follows that there exist two vertices $u$ and $v$ of $D$ that are distance at most 3 apart in $T$, say joined by path $P$. Construct a maximal matching $M$ by starting with the first edge of $P$ and, if the length of $P$ is 3, also the last edge of $P$. Extend to a maximal matching arbitrarily.

Create a dominating set $D'$ of $T - M$ as follows. Start with $D' = D$. For every vertex of $D$ other than $u$ or $v$, they lose at most one neighbor when $M$ is removed; if they do lose a neighbor, add that neighbor to $D'$. At this point $|D'| \leq 2|D| - 2$. The only possible vertices not dominated by $D'$ are the neighbors of $u$ and $v$ in $M$; call these $u'$ and $v'$ respectively. If $u$ and $v$ are adjacent in $T$, then we constructed $M$ to include the edge $uv$, and $D'$ to include both $u$ and $v$, and so there is no undominated vertex. If $u$ and $v$ are at distance 2 in $T$, then $u'$ is dominated by $v$, and so only $v'$ is not dominated by $D'$, and we can add it to $D'$. If $u$ and $v$ are at distance 3, then $u'$ and $v'$ are the undominated vertices. But they are adjacent, and so can be dominated by adding one of them to $D'$. In all cases it follows for the final $D'$ that $|D'| < 2|D|$. 

12
The bound in Theorem 6 is best possible. That is, for all $r \geq 2$ there is a connected graph with $\gamma(G) = r$ and for every maximal matching $M$ of $G$ it holds that $\gamma(G - M) \geq 2r - 1$. For example, consider the octopus $O_r$ defined above and a maximal matching $M$ of $O_r$. By the maximality of $M$, it must contain an edge incident with every support vertex. It follows that a dominating set of $O_r - M$ must contain at least two vertices from each subdivided edge, and one more vertex to dominate the end-vertex neighbor of the center. That is, $\gamma(O_r - M) \geq 2r - 1$.

2.3 Trees With Unique $\gamma$-Sets

We observed earlier that if a tree has a $\gamma$-set where every vertex is adjacent to at least two end-vertices, then the tree has a matching whose removal doubles the domination number. Such a tree is a special case of a tree with a unique $\gamma$-set. However, it is not the case that having a unique $\gamma$-set forces there to be a “doubling matching”. The smallest example is the path $P_9$, where $\gamma = 3$ but the removal of a matching can only increase the domination number to 5.

It is immediate that if a graph has a unique $\gamma$-set, then the bondage number is 1 (first observed in [12]) and hence there is a matching whose removal increases the domination number. But one can say more in trees.

**Theorem 7.** If a tree $T$ has a unique $\gamma$-set, then there is a matching $M$ in $T$ such that $\gamma(T - M) > \frac{3}{2} \gamma(T)$.

This result is best possible as shown by the paths $P_{3m}$ for $m$ odd. Then $\gamma(P_{3m}) = m$, but removing a matching can only increase the domination number to $(3m + 1)/2$.

For the proof of Theorem 7, it is easier to work in a slightly more general setting. Gunther et al. [6] observed that in any graph if $D$ is the unique $\gamma$-set (and there are no isolated vertices), then every vertex in $D$ has (at least) two external private neighbors. Thus Theorem 7 follows from the following theorem. (Note that the statement of the theorem does not require $D$ to be dominating.)

**Theorem 8.** If a tree $T$ has a set $D$ such that every vertex in $D$ has at least two external private neighbors, then there is a matching $M$ in $T$ such that $\gamma(T - M) > \frac{3}{2} |D|$.

**Proof.** The proof is by induction on the order of $T$. Trivially we may assume $D$ is not empty. Indeed:
Claim 1. We may assume that every support vertex is in \(D\).

The condition on \(D\) precludes an end-vertex \(x\) from being in \(D\). So if such \(x\) is not dominated by \(D\), just delete it from \(T\) and apply the induction hypothesis (and note that deleting an end-vertex cannot increase the domination number).

Consider the base case. If each vertex in \(D\) has two neighbors that are end-vertices, then the matching \(M\) consisting of one leaf-edge incident with each vertex of \(D\) is such that \(\gamma(T - M) \geq 2|D|\). It follows that we may assume the diameter of \(T\) is at least 5. If the diameter is exactly 5 and there is a vertex in \(D\) without two end-vertex neighbors, then let \(M\) consist of the central edge and one leaf-edge incident with each vertex of \(D\), and again it follows that \(\gamma(T - M) \geq 2|D|\). So we may assume the diameter is at least 6.

For the inductive step, most of the time we proceed as follows. We identify a subset \(S\) of the vertices such that \(T' = T - S\) is a tree that satisfies the hypothesis with \(D - S\). The inductive hypothesis yields a matching \(M'\) of \(T'\), which we extend to a matching \(M\) of \(T\) by adding a set \(N\) of edges all of whose ends are in \(S\). Further, \(S\) and \(M\) are such that the vertices of \(T'\) that have a neighbor in \(S\) can be dominated in \(T - M\) by one vertex of \(V(T')\). We say \(S\) and \(M\) with all the above properties are standard.

For any subset \(S\) and matching \(M\), let \(\psi^M_S\) denote the minimum possible number of vertices of \(S\) in any dominating set of \(T - M\).

Claim 2. Let \(S\) and \(M\) be standard.

(a) It holds that \(\gamma(T - M) \geq \psi^M_S + \gamma(T' - M') - 1\).

(b) If \(\psi^M_S \geq \frac{3}{2}|D \cap S| + 1\), then the inductive step is valid.

(c) Further, if no set that achieves \(\psi^M_S\) has a neighbor in \(V(T')\), then for the inductive step it is sufficient that \(\psi^M_S \geq \frac{3}{2}|D \cap S|\).

(a) Consider a \(\gamma\)-set of \(T - M\) and let \(X\) be the restriction of it to \(V(T')\). Then \(|X| \leq \gamma(T - M) - \psi^M_S\). Further, \(X\) dominates all of \(T' - M\) except possibly those vertices of \(T'\) with neighbors in \(S\), and these can be dominated by one vertex of \(V(T')\) by the definition of standard. Thus \(\gamma(T' - M') \leq |X| + 1\). It follows that \(\gamma(T - M) - \psi^M_S \geq \gamma(T' - M') - 1\), which re-arranged gives one the desired inequality.

(b) We have that \(\gamma(T - M) \geq \psi^M_S + \gamma(T' - M') - 1 > \psi^M_S + \frac{3}{2}(|D - S|) - 1 = \frac{3}{2}|D| + \psi^M_S - \frac{3}{2}|D \cap S| - 1\).
The claim follows.

c) The calculation is similar, except that \( \gamma(T - M) \geq \varsigma^M_S + \gamma(T' - M') \).

It is common in trees to induct by focussing on the vertices at the end of a longest path. We
generalize this slightly. Given a pair of adjacent vertices \( v \) and \( w \), we define a \((v, w)\)-peripheral path
as a path starting with edge \( vw \) of longest possible length, and call its length the \((v, w)\)-peripheral
length. For a vertex \( v \) that is not an end-vertex, we define the peripherality of \( v \), denoted \( \text{per}(v) \),
by considering the multiset of \((v, w)\)-peripheral lengths for all neighbors \( w \), and taking the second-
largest length (which might equal the largest). We define \( \text{per}(v) = 0 \) if \( v \) is an end-vertex. For
example, if \( v_0v_1\ldots v_d \) is a longest path in \( T \), then \( \text{per}(v_i) = \text{per}(v_{n-i}) = i \) for \( 0 \leq i \leq d/2 \). Further,
we designate the neighbor \( w \) of \( v \) with the largest \((v, w)\)-peripheral length its free neighbor. Note
that, if the diameter of \( T \) is more than \( 2 \text{per}(v) \), then the free neighbor of \( v \) is uniquely determined;
otherwise designate one arbitrarily, if necessary.

We continue the proof of the theorem. Since the diameter is at least 6 there is some vertex
\( v_3 \) with \( \text{per}(v_3) = 3 \). Note that in all the figures in the proof of this theorem, solid vertices are
vertices that are definitely in \( D \) and hollow vertices are vertices that are definitely not in \( D \).

**Claim 3.** If \( \text{per}(v_3) = 3 \) with peripheral path \( v_3v_2v_1v_0 \), then we may assume both \( v_1 \) and \( v_2 \) have
degree 2.

By Claim 1, \( v_1 \in D \).

(i) We first prove that \( v_1 \) has degree 2. So suppose that \( v_1 \) has at least two end-vertex
neighbors. There are three cases.

*Case A: Assume \( v_2 \) is in \( D \) and \( v_2 \) has two end-vertex neighbors.* Then induct with \( S \)
consisting of all vertices separated from \( v_2 \) by the bridge \( v_1v_2 \), and \( N = \{v_0v_1\} \). (See Figure 2.6a
for an example.) It is immediate that \( \psi^M_S = 2 \) while \( |D \cap S| = 1 \). Since one may assume that \( v_2 \) is
in the dominating set of \( T - M \) (as it has an end-vertex neighbor), the bound holds by Claim 2b.

*Case B: Assume \( v_2 \) is in \( D \) but has only one end-vertex neighbor.* Then \( v_3 \) must be the
other external private neighbor of \( v_2 \). Let \( v_4 \) be the free neighbor of \( v_3 \). Then, by the peripherality
of \( v_3 \), all other neighbors of \( v_3 \), if any, are within distance 2 of an end-vertex. Since \( v_3 \) has no
other neighbor in \( D \) and is not in \( D \) itself, it follows that each of these neighbors must be distance
exactly 2 from an end-vertex, have a neighbor in \( D \) and all other neighbors of that neighbor must
be end-vertices. (See Figure 2.6b for an example.) Induct with \( S \) consisting of all vertices separated
from $v_4$ by the bridge $v_3v_4$, and $N$ consisting of one leaf-edge incident with each vertex in $D \cap S$. Then every vertex of $D \cap S$ except $v_2$ has two end-vertex neighbors in $T$ and hence at least one end-vertex neighbor in $T - M$; thus $\psi^M_S = 2|D \cap S| - 1$. However, any set achieving this does not dominate $v_4$. So the bound holds by Claim 2b, since $|D \cap S| \geq 2$.

Case C: Assume $v_2 \not\in D$. By the peripherality of $v_3$, it must be that any neighbor of $v_2$, other than $v_3$, is in $D$ and has at least two end-vertex neighbors. (See Figure 2.6c for an example.) Induct with $S$ consisting of all vertices separated from $v_3$ by the bridge $v_2v_3$, and $N$ consisting of one leaf-edge incident with each vertex of $D \cap S$. We have $\psi^M_S = 2|D \cap S|$; but a set achieving this cannot dominate $v_3$. So the bound holds by Claim 2b.

Hence we have shown that one may assume that $v_1$ has degree 2.

(ii) It follows that $v_2$ is the external private neighbor of $v_1$. Thus $v_2$ cannot have another neighbor with peripherality at most 1, and so it has degree 2.

It follows that a vertex of peripherality 3 cannot be in $D$.

Claim 4. We may assume that every vertex $v_3$ of peripherality 3 has degree 2.

Let $v_3v_2v_1v_0$ be a peripheral path, and let $v_4$ denote the free neighbor of $v_3$. Suppose $v_3$ has a third neighbor $w$.

(i) Assume that $w$ has peripherality 2. Then by Claim 3, $w$ has degree 2 and its other neighbor has degree 2 too. Then induct with $S$ consisting of the vertices separated from $v_3$ by the bridge $v_2v_3$ together with the vertices separated from $v_3$ by the bridge $wv_3$, and $N$ consisting of a leaf-edge incident with each vertex of $D \cap S$. (See Figure 2.7a.) It follows that $\psi^M_S = 4$ while $|D \cap S| = 2$, and so the bound holds by Claim 2a.

(ii) Assume that $w$ has peripherality 1 and two end-vertex neighbors. Then induct as in the previous case.
(iii) Assume $v_3$ has no neighbor of these two types. It follows that $w$ has peripherality 1 and only one end-vertex neighbor, and thus that $v_3$ is an external private neighbor of $w$. In particular, $v_3$ has degree 3. (See Figure 2.7b.) Then induct with $S$ consisting of the vertices separated from $v_4$ by the bridge $v_3v_4$, and $N$ consisting of $v_0v_1$, $v_2v_3$, and the leaf-edge incident with $w$. It follows that $\psi^M_S = 4$ while $|D \cap S| = 2$, and so the bound holds by Claim 2b.

If the tree has diameter 6 or 7, then it follows from the above claim that $T$ is a path, that is, $P_7$ or $P_8$. It is easy to observe that the largest $D$ satisfying the hypothesis of the theorem has two vertices, and that removing a maximum matching yields a forest with domination number at least 4. So we may assume that $T$ has diameter at least 8. In particular, there exists some vertex $v_4$ with $\text{per}(v_4) = 4$.

**Claim 5.** We may assume that every vertex $v_4$ of peripherality 4 is in $D$ and has degree 2.

Let $v_4v_3v_2v_1v_0$ be a peripheral path.

(i) Suppose that $v_4 \not\in D$. Then induct with $S = \{v_0, v_1, v_2, v_3\}$ and $N = \{v_0v_1, v_2v_3\}$. Then $\psi^M_S = 2$ and no set achieving this contains $v_3$, while $|D \cap S| = 1$. Thus the bound follows from Claim 2c. So we may assume $v_4$ is in $D$.

(ii) Suppose $v_4$ has degree more than 2. Let $v_5$ be its free neighbor. Let $m$ be the length of the longest path that starts with $v_4$ and does not use $v_3$ or $v_5$. Since $\text{per}(v_4) = 4$, it follows that $m \leq 4$. There are four cases.

**Case A:** $m = 4$. Say we have path $v_4w_3w_2w_1w_0$. Then $\text{per}(w_3) = 3$, and so by the above claim has degree 2. We use a non-standard inductive step. Let $S = \{v_0, v_1, v_2, w_0, w_1, w_2\}$. (See Figure 2.8a.) Then induct on $T' = T - S$ to produce matching $M'$. Then, since $M'$ can contain only one edge incident with $v_4$, we may assume without loss of generality that the edge $v_3v_4$ is not in $M'$. So we can define $N = \{v_0v_1, v_2v_3, w_0w_1\}$. It follows that $\psi^M_S = 4$, but only one vertex of $T'$
can be dominated by $S$ in $T - M$. Thus $\gamma(T - M) \geq \gamma(T' - M') + 3$, while $|D \cap S| = 2$, and so the bound follows.

![Diagrams](attachment:image.png)

Figure 2.8: Three possible choices of $S$

**Case B:** $m = 3$. Say we have path $v_4w_2w_1w_0$. Then $w_1$ is a support vertex and so it is in $D$; and thus $w_1$ has (at least) two end-vertex neighbors, while $w_2$ is not an external private neighbor of $v_4$. Indeed, $\text{per}(y) \leq 1$ for all neighbors $y$ of $w_2$ other than $v_4$. Again we use a non-standard inductive step. Let $S$ consist of $v_0, v_1, v_2$ together with all vertices separated from $v_4$ by the bridge $w_2v_4$. (See Figure 2.8b.) Then induct on $T' = T - S$ to produce matching $M'$. Now form $M^*$ from $M'$ by deleting edge $v_3v_4$ if present. Then form $M$ from $M^*$ by adding $v_2v_3$ and one leaf-edge incident with each vertex of $D \cap S$. Then $\psi^M_S = 2|D \cap S|$. But since in $T - M$ vertex $v_3$ is an end-vertex adjacent to $v_4$, we may assume $v_4$ is in the dominating set of $T - M$; thus a set achieving $\psi^M_S$ cannot help with dominating $V(T')$. It follows that $\gamma(T - M) \geq \psi^M_S + \gamma(T' - M^*) \geq \psi^M_S + \gamma(T' - M') - 1$, and the bound follows since $|D \cap S| \geq 2$.

**Case C:** $m = 2$. Say we have path $v_4w_1w_0$. Then $w_1$ is in $D$ and has (at least) two end-vertex neighbors. Again we use a non-standard inductive step. Let $S$ consist of $v_0, v_1, v_2$ together with all vertices separated from $v_4$ by the bridge $w_1v_4$. (See Figure 2.8c.) Then induct on $T' = T - S$ to produce matching $M'$. Now, form $M^*$ from $M'$ by deleting edge $v_3v_4$ if present. Then form $M$ from $M^*$ by adding edges $v_0v_1, v_2v_3$, and $w_0w_1$. Then $\psi^M_S = 4$ while $|D \cap S| = 2$; and by a similar argument to the previous case, it follows that $\gamma(T - M) \geq \psi^M_S + \gamma(T' - M^*) \geq \psi^M_S + \gamma(T' - M') - 1$, and the bound follows similarly.

**Case D:** $m = 1$. That is, all other neighbors of $v_4$ are end-vertices. Then induct with $S$ consisting of all vertices separated from $v_5$ by the bridge $v_4v_5$, and $N$ consisting of a leaf-edge incident with each of $v_1$ and $v_4$. Again $\psi^M_S = 4$ while $|D \cap S| = 2$. Thus the claim holds.

If the tree has diameter 8 or 9, then it follows from the above claim that $T$ is a path, that
is, $P_9$ or $P_{10}$. It is easy to observe that the largest $D$ satisfying the hypothesis of the theorem has three vertices, and that removing a maximum matching yields a forest with domination number at least 5. So we may assume that $T$ has diameter at least 10. In particular, there exists some vertex $v_5$ with $\text{per}(v_5) = 5$.

Say $v_5$ has peripheral path $v_5v_4v_3v_2v_1v_0$ and free neighbor $v_6$. Let $y$ be a neighbor of $v_5$ other than $v_6$, if it exists. Then $\text{per}(y) \leq 4$. Since $v_5$ cannot have a second neighbor in $D$, it follows that $y$ is not in $D$. Hence by the above claim $\text{per}(y) \neq 4$. Also $y$ does not have an end-vertex neighbor. It follows that, for each neighbor $z$ of $y$ apart from $v_5$, $\text{per}(z) \leq 2$. If $\text{per}(z) = 2$ then $\text{per}(y) = 3$, and so $z$ is not in $D$. (See Figure 2.9.) If there is a $z$ with $\text{per}(z) = 1$ that does not have at least two end-vertex neighbors, then it is the only $z$ with $\text{per}(z) = 1$. Induct with $S$ consisting of all vertices separated from $v_6$ by the bridge $v_5v_6$, and $N$ consisting of $v_0v_1$, $v_2v_3$, $v_4v_5$, and one leaf-edge incident with each vertex in $(D \cap S) - \{v_1, v_4\}$. Then $\psi^M_S = 2|D \cap S| - 1$ and any set achieving this does not contain $v_5$. So the bound follows from Claim 2c, since $|D \cap S| \geq 3$.

![Figure 2.9: One possible choice of $S$](image)

If $y$ does not exist, then induct similarly with $S = \{v_0, \ldots, v_5\}$.

This concludes the proof. \hfill \square

### 2.4 Trees where Matching Removal Has Little Impact

We considered earlier the case where the removal of a matching doubles or nearly doubles the domination number. We consider here the other extreme but only for trees. We show first that there is always a matching whose removal increases the domination number.

We will need the following fact, originally obtained by Bollobás and Cockayne, and include our own version of a standard proof:
Lemma 3. [1] The domination number of a graph without isolated vertices is at most its matching number.

Proof. Let $G$ be a graph without isolated vertices and let $D$ be a $\gamma$-set. We want to change $D$ into a dominating set such that every vertex in the set has an external private neighbor. For every vertex $v \in D$, $v$ must have a neighbor not in $D$ else we could remove it from $D$ (contradicting minimality). If its neighbor is an external private neighbor then leave it alone. Suppose then that $v$ has no external private neighbors. Then every vertex in $N(v)$ is dominated by another vertex in $D$. Also, $N(v)$ has no vertices in $D$, else again we could remove $v$ from $D$. So remove $v$ from $D$ and let any vertex $u$ in $N(v)$ enter $D \setminus \{v\}$. We see that $v$ is an external private neighbor of $u$. We can continue this process for every vertex in our dominating set to obtain a dominating set $D'$ such that every vertex in that set has an external private neighbor.

Now we construct a matching $M$ by matching every vertex in $D'$ with an external private neighbor. We can extend $M$ to a maximal matching $M'$ which has cardinality less than or equal to the matching number of $G$ and thus $\gamma(G) \leq M(G)$. 

This yields the following:

Theorem 9. Removing any maximum matching $M$ from a nontrivial tree $T$ increases the domination number.

Proof. It is immediate that $T - M$ has $|M| + 1$ components. Thus $\gamma(T - M) \geq |M| + 1$, since we need at least one vertex in each component. By the above lemma, $|M| \geq \gamma(T)$.

As noted earlier, it is not true that every maximal matching removal increases the domination number.

We next consider the trees where removing any maximal matching only increases the domination number by at most 1. We have already seen that the star is an example. We define two families of trees:

- Let $S$ denote the set of all trees that have radius at most two and at most one vertex of degree more than 2. We call the vertex of degree more than 2 the “hub”.
Let $\mathcal{T}$ denote the set of all trees obtained from a tree of diameter 3 by subdividing each edge once. (Note that all trees in $\mathcal{T}$ have odd order.) We call the starting tree the base tree.

Figure 2.10 gives a picture of a tree in $\mathcal{S}$ and a tree in $\mathcal{T}$.

![Figure 2.10: A tree in $\mathcal{S}$ and in $\mathcal{T}$](image)

**Lemma 4.** If $T$ is a tree in $\mathcal{S} \cup \mathcal{T}$, then the removal of a matching $M$ from $T$ either leaves the domination number unchanged or increases it by 1.

**Proof.** Assume $T \in \mathcal{S}$. Then $\gamma(T)$ equals the number of vertices of degree 2, plus one if the hub has a neighbor that is an end-vertex. Further, $\gamma(T - M)$ is at most the number of vertices of degree 2 plus one for the hub, plus one if $M$ contains an edge joining the hub to an end-vertex neighbor.

Assume $T \in \mathcal{T}$ with order $n$. Then $\gamma(T) = (n - 1)/2$ as, for example, the end-vertices and the central vertex form a dominating set while we need a different vertex to dominate each of them. On the other hand, $\gamma(T - M) \leq (n + 1)/2$, as the original vertices of the base tree dominate $T$ even after the removal of a matching.

It is well-known and trivial that adding an edge to a graph can reduce the domination number by at most 1.

**Theorem 10.** A tree $T$ has the property that $\gamma(T - M) \leq \gamma(T) + 1$ for all matchings $M$ if and only if $T$ is in $\mathcal{S} \cup \mathcal{T}$.

**Proof.** Let us say a matching is “bad” if its removal increases the domination number by more than 1, and a tree is “good” if it has no bad matching. By Lemma 4, it remains to show that if a tree $T$ is good then it is in one of the two families. The proof is by induction on the order of $T$.
For the base case consider a tree of diameter at most 3. If such a tree has at most one vertex of degree more than 2, then it is in $\mathcal{S}$. If such a tree has two vertices of degree more than 2, then a maximum matching is bad. Hence we may assume $T$ has diameter at least 4.

Consider a longest path $P$ of good $T$ with penultimate edge $uv$ where all other neighbors of $v$ are end-vertices. Say $T - uv$ consists of trees $T_u$ and $T_v$. By Theorem 9, there exists a matching of $T_u$ whose removal increases the domination number of $T_u$; let $M_u$ be any such matching (not necessarily maximum). Extend $M_u$ to matching $M$ of $T$ by adding a leaf-edge incident with $v$. Then

$$\gamma(T - M) \geq \gamma(T_u - M_u) + 1 > \gamma(T_u) + 1 \geq \gamma(T).$$

In particular, $\gamma(T - M) = \gamma(T) + 1$ requires both that $\gamma(T) = \gamma(T_u) + 1$ and that $\gamma(T_u - M_u) = \gamma(T_u) + 1$. Since $M_u$ was any matching such that $\gamma(T_u - M_u) > \gamma(T_u)$, this implies that $T_u$ is good, and thus $T_u \in \mathcal{S} \cup T$.

Let $D_\ell$ denote the set of support vertices of $T$, let $M_\ell$ be a matching consisting of a leaf-edge incident with each support vertex, and let $U_\ell$ be the tree obtained from $T$ by removing each end-vertex incident to an edge of $M_\ell$. We say that the tree $T$ is leafy if $D_\ell$ forms a dominating set. If so, $\gamma(T - M_\ell) = |M_\ell| + \gamma(U_\ell) = \gamma(T) + \gamma(U_\ell)$. So $U_\ell$ must have $\gamma(U_\ell) = 1$ and thus be a star if $T$ is leafy.

Assume first that $T_u \in \mathcal{S}$. If $T_u$ is a star, then $T$ is leafy and $\gamma(T) = 2$. It is easily checked that the only way $T$ can be good is that it is $P_5$, which is in $\mathcal{S}$. So assume $T_u$ is not a star. In $T_u$, let $a$ be a vertex at distance 2 from the hub, $c$ the hub, and $b$ their common neighbor. Let $d$ be an end-vertex neighbor of the hub, if it exists.

Up to symmetry there are four possibilities for $u$. (a) Assume $u = a$. Then $vabc$ is in $U_\ell$, and so $T$ is not leafy; thus the hub has no end-vertex neighbor. So if $v$ has degree 2 in $T$ the tree $T$ is in $\mathcal{T}$. Otherwise it can be checked that any maximal matching containing the edge $bc$ and a leaf-edge incident with $v$ is bad. (b) Assume $u = b$. Then $T$ is leafy. The only way $U_\ell$ can be a star is that both $v$ and $c$ have degree 2 in $T$, and $c$’s other neighbor is an end-vertex; so $T$ is in $\mathcal{S}$. (c) Assume $u = c$. Then $T$ is leafy. If $v$ has degree 2 in $T$ then $T$ is in $\mathcal{S}$; otherwise $U_\ell$ is not a star. (d) Assume $u = d$. Then $T$ is leafy, but $U_\ell$ is not a star, which contradicts the above.

Assume second that $T_u \in \mathcal{T}$. By the choice of $P$, $u$ cannot be the central vertex of $T_u$. If $u$ is an end-vertex of $T_u$, then it is easily checked that $\gamma(T) = \gamma(T_u)$, which contradicts the above. If
$u$ is a subdivision vertex in $T_u$, then one can check that there is maximum matching whose removal increases the domination number of $T$ by 2. If $u$ is one of the large-degree vertices, then we are in $\mathcal{T}$ if $v$ has degree 2 in $T$, and there is a bad matching otherwise.
Chapter 3

Further Thoughts

There are several directions to consider further. In this thesis we study the effects of removing a matching from a graph on the domination number. This is of course a special case of more general questions such as: what is the smallest $k$ such that there exists a subset of edges, inducing a subgraph with maximum degree $k$, whose removal increases $\gamma$ by at least $\ell$? Alternatively, if one wants to remain in the realm of removing matchings one can ask if sharper bounds can be obtained for other families of graphs? Even for trees, one could restrict the maximum degree and then ask about better bounds for the impact of matching removal. There is also the question of an algorithm for finding a matching in a tree whose removal increases the domination number the most, and the complexity of that task in general graphs (recall that Figure 2.2 shows it is not as simple as taking a maximum matching). We noted that if every vertex has two leaf neighbors then there is a doubling matching. One could try to classify the family of graphs exactly that have a doubling matching. Lastly we also note that we could consider the effects of removing a matching on other domination related parameters. Notably one can consider how the removal of a matching affects the independence number, the total domination number, and the independent domination number which was explored in [3].
